Quantum Mechanics and Stellar Spectroscopy
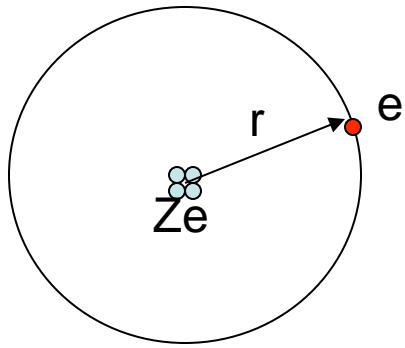

http://apod.nasa.gov/apod/

Recall the electric force. Like gravity it is
a "$1/r^2$" force/ That is:

$$F_{elec} = \frac{Z_1 Z_2 e^2}{r^2}$$

where Z_1 and Z_2 are the (integer) numbers of
electronic charges. Similarly, the electric potential
energy is

$$E_{elec} = -\frac{Z_1 Z_2 e^2}{r}$$

Rutherford Atom (1911)

$$F_{elec} = F_{cent}$$

$$\frac{Ze^2}{r^2} = \frac{m_e v^2}{r} \implies \boxed{r = \frac{Ze^2}{m_e v^2}}$$
$$Z = 1, 2, 3, \ldots$$

classically, any value of v or r is allowed. Much like planets.

Protons in nucleus. Electrons orbit like planets. The neutron was not discovered until 1932 (Chadwick)

Rutherford Atom (1911)

$$F_{elec} = F_{cent}$$

$$\frac{Ze^2}{r^2} = \frac{m_e v^2}{r} \Rightarrow \boxed{r = \frac{Ze^2}{m_e v^2}}$$

$$Z = 1,2,3,\ldots$$

Protons in nucleus. Electrons orbit like planets. The neutron was not discovered until 1932 (Chadwick)

Total energy:

classically, any value of v or r is allowed.

$$E_{tot} = KE + PE = \frac{m_e v^2}{2} - \frac{Ze^2}{r}$$
$$KE = \frac{1}{2} m_e v^2 = \frac{Ze^2}{2r}$$

$$= \frac{Ze^2}{2r} - \frac{Ze^2}{r} = -\frac{Ze^2}{2r}$$

$$\boxed{v = \sqrt{\frac{Ze^2}{m_e r}}}$$

i.e., $\boxed{2KE = -PE}$ (if PE is negative)

Virial theorem still works for the electric force.

Rutherford Atom (1911)

$$v = \sqrt{\frac{Ze^2}{m_e r}} \qquad F = m_e a = \frac{m_e v^2}{r}$$

$$a = \frac{v^2}{r} = \frac{Ze^2}{m_e r^2} \qquad E_{tot} = -\frac{Ze^2}{2r}$$
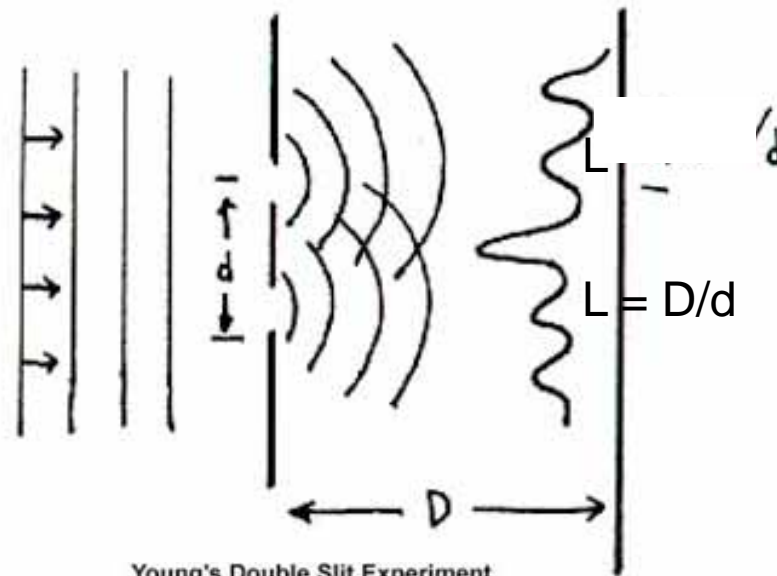

BUT,

As the electron moves in its orbit it is accelerated, and therefore emits radiation. Because energy is being radiated, the total energy of the system must decrease – become more negative.
This means r must get smaller and v must increase. But smaller r and larger v also imply greater acceleration and radiation.
In approximately 10^{-6} s the electron spirals into the nucleus. Goodbye universe…

The solution lies in the wave-like property of the electron – and of all matter
For wavelike phenomena e.g., light, "interference" is expected

$L = D/d$

L

D

Thomas Young early 1800's for light.

Same basic result obtained using electrons…

$$\lambda = \frac{h}{p}$$

8e⁻   270e⁻
Single-electron Build-up of Interference Pattern

2,000e⁻   60,000e⁻

Hitachi labs (1989)

.

In 1924, Louis-Victor de Broglie formulated the DeBroglie hypothesis, claiming that all matter, not just light, has a wavelike nature. He related the wavelength (denoted as λ) and the momentum (denoted as p)

$$\lambda = \frac{h}{p}$$

A property of our universe

This is a little like the relation we had for photons

$$E = h\nu$$

$$= hc/\lambda$$

but if

$$E = pc$$

$$\lambda = \frac{h}{p}$$

Light and particles like the electron (and neutron and proton) all have wavelengths and the shorter the wavelength the higher the momentum p. Electrons always have some motion regardless of their temperature
The condition that a particle cannot
be localized to a region Δx smaller
than its wavelength $\lambda =$ h/p also implies

$$\lambda < \Delta x \implies p \, \Delta x > h \implies p > \frac{h}{\Delta x}$$

One cannot confine a particle to a
region Δx without making its momentum
increase

$$p = \frac{h}{\Delta x} \quad \text{is the "degenerate" limit}$$

Consider one electron in a contracting box

As you squeeze on the box, the particle
in the box has to move faster.

$$\lambda = \frac{h}{p} = \frac{h}{mv}$$

$$\lambda \downarrow \ \Rightarrow \ v \uparrow$$

The squeezing provides the energy to increase v

A little thought will show how this is going to solve
our problem with the stability of matter.

As the electron is forced into a smaller and smaller
volume, it must move faster. Ultimately this kinetic
energy can support it against the electrical attraction
of the nucleus.

$$\text{Since } p = \frac{h}{\lambda} \implies \frac{1}{2} m_e v^2 = \frac{p^2}{2m_e} \propto \frac{1}{\lambda^2} \sim \frac{1}{r^2}$$

$$\text{but} \quad -\frac{Ze^2}{r} \propto \frac{1}{r}$$

There comes a minimum radius where the electron
cannot radiate because the sum of its potential
and kinetic energies has reached a minimum.

At large distance electrical repulsion dominates. At short distances the quantum mechanical kinetic energy is larger.

$KE \propto \dfrac{1}{r^2}$

$PE \propto \dfrac{1}{r}$
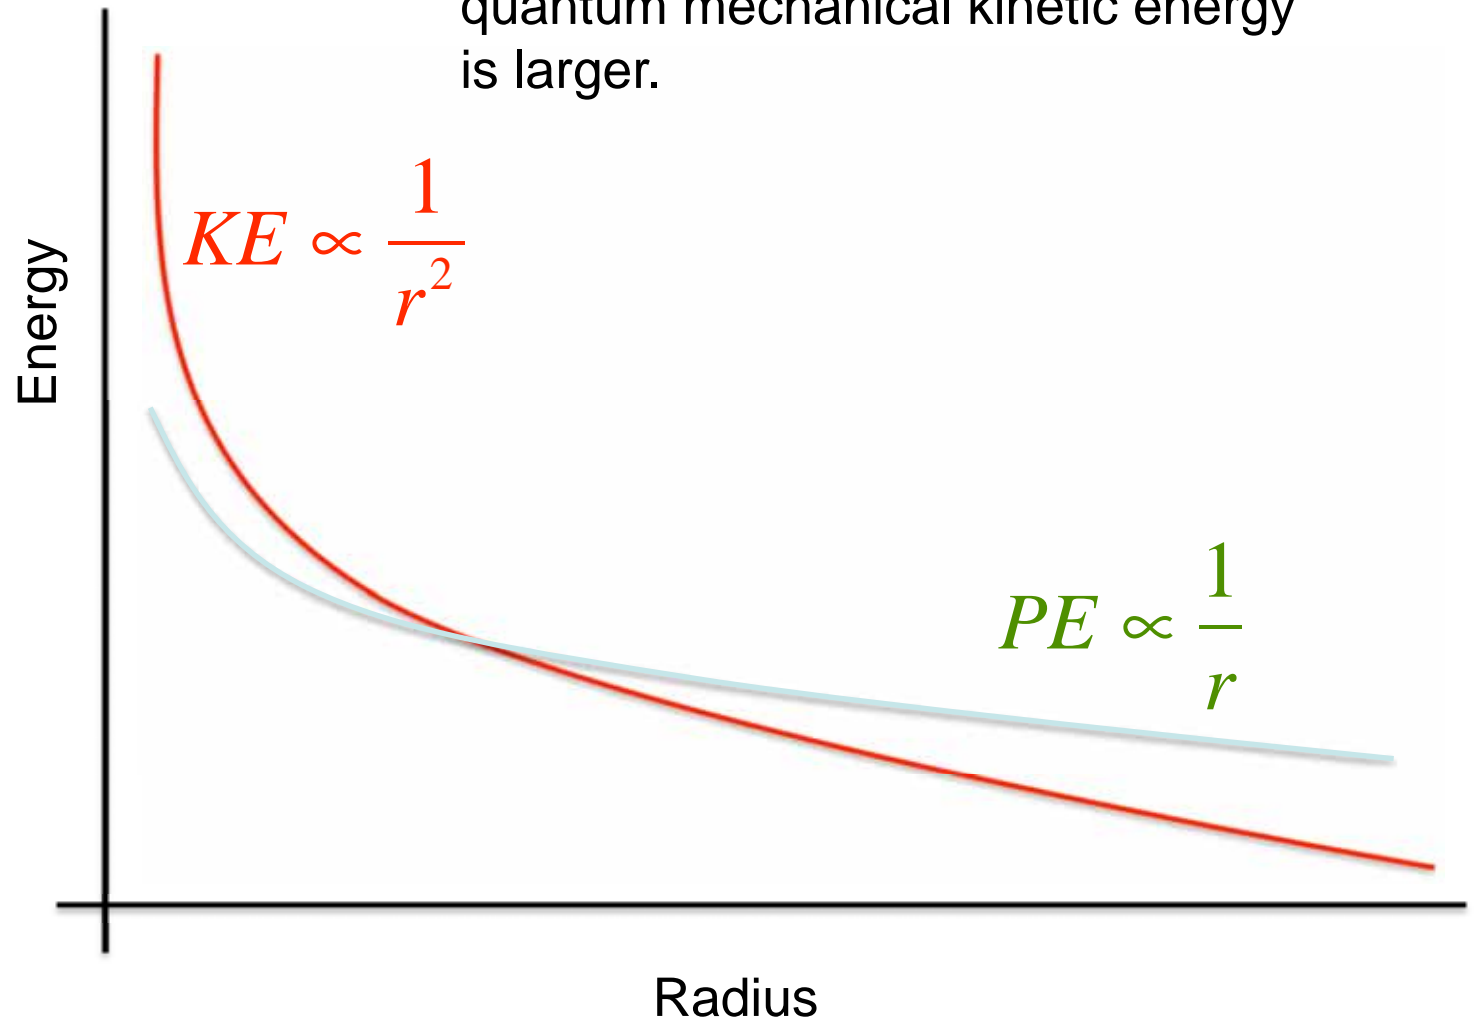

Energy

Radius

Ground state of the hydrogen atom – Neils Bohr (1913)

(lowest possible energy state)

Must fit the wavelength of the electron inside a circle of radius r,
the average distance between the electron and the proton.

$$\lambda = 2\pi r$$

$$= \frac{h}{p}$$

The 2π here is rather arbitrary but gives the right answer.

e^- + p

$$\therefore p = \frac{h}{\lambda} = \frac{h}{2\pi r}$$

$$KE = \frac{mv^2}{2} = \frac{m^2 v^2}{2m} = \frac{p^2}{2m} = \frac{h^2}{2m(4\pi^2 r^2)}$$ new

$$PE = -\frac{e^2}{r}$$ as before

Note that PE goes as $1/r$ and KE goes as $1/r^2$

Energy

$KE \propto \dfrac{1}{r^2}$

$-PE \propto \dfrac{1}{r}$

r_o

r

For a single electron bound to a single proton, i.e., hydrogen.

At r_o

$$KE = -\frac{1}{2} PE$$

$$\frac{h^2}{2m_e (4\pi^2 r_0^2)} = \frac{Ze^2}{2r_o}$$

$$\frac{h^2}{2m_e Ze^2} = \frac{4\pi^2 r_0^2}{2r_o}$$

$$\boxed{r_o = \frac{h^2}{4\pi^2 Z e^2 m_e}}$$

$$i.e., \ p = \frac{h}{2\pi r} \ \text{and} \ KE = \frac{1}{2} m_e v^2 = \frac{(m_e v)^2}{2m_e}$$
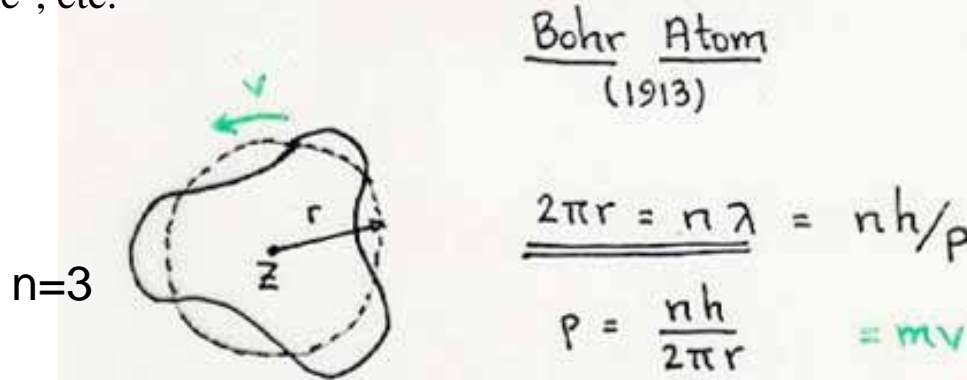

$$= \frac{p^2}{2m_e}$$

Energy would have to be provided to the electron to make it move any closer to the proton (because it would have to move faster), more energy than e^2/r can give.

For Z=1 (hydrogen) $r_o = 0.529189379 \, \overset{o}{A} = 5.29189379 \, x10^{-9} \, cm$

Bohr's First Postulate

For atoms with a single electron – H, He$^+$, etc.

Bohr Atom (1913)

$$2\pi r = n\lambda = \frac{nh}{p}$$

$$p = \frac{nh}{2\pi r} = mv$$

n=3

The only possible states of the electron are those for which

$$mvr = \frac{nh}{2\pi}$$

Solve as before:

$$r = \frac{n^2 h^2}{4\pi^2 Z e^2 m_e} = 0.53\,\frac{n^2}{Z}\ \text{Angstroms}$$

$$E_{tot} = -\frac{Ze^2}{2r} = -\frac{2\pi^2 Z^2 e^4 m_e}{n^2 h^2}$$

$$E_{tot} = -13.6\ \text{eV}\left(\frac{Z^2}{n^2}\right)$$

$$1\text{eV} \equiv 1.602 \times 10^{-12}\ \text{erg}$$

n = 1 is the "ground state"

For atoms with only a single electron.

For hydrogen Z = 1

n = 1

n=2

n=3

*

In the full quantum mechanical solution the electron is described by a "wave function" that gives its probability for being found at any particular distance from the nucleus.
In the simplest case these distributions are spherical.

The radius in the Bohr model is the average radius but the energy is precise.
n=1   n=2, l=1, m=0   n=2, l=1, m=1

*

n = 1, l = 0, m = 0

All orbitals from n = 1 through 4
Number electrons per shell is $2n^2$, but
don't always completely fill one shell
before starting on the next.

Bohr's Second Postulate

$n=3$

$n=2$

$n=1$

-e

+Ze

$\Delta E = h\nu$

Only the "ground state", n = 1, is permanently stable

Bohr's Second Postulate

Radiation in the form of a single quantum (photon) is
Emitted (or absorbed) as the electron makes a transition
From one state to another. The energy in the photon is the
Difference between the energies of the two states.

emission   absorption

$$\mathrm{E}_m \rightarrow \mathrm{E}_n + h\nu \qquad (\text{or } \mathrm{E}_n + h\nu \rightarrow \mathrm{E}_m) \quad m > n$$

$$h\nu = \frac{hc}{\lambda} = E_m - E_n$$

$$\frac{1}{\lambda} = \frac{E_m - E_n}{hc} = \frac{2\pi^2 Z^2 e^4 m_e}{h^3 c}\left(\frac{1}{n^2} - \frac{1}{m^2}\right)$$

$$\frac{1}{\lambda_{mn}} = 1.097\times10^5 \; Z^2 \left(\frac{1}{n^2} - \frac{1}{m^2}\right) \; \mathrm{cm}^{-1}$$

$$\lambda_{mn} = \frac{911.6 \; A}{Z^2}\left(\frac{1}{n^2} - \frac{1}{m^2}\right)^{-1}$$

(for atoms with only one electron)

$$\lambda_{mn} = \frac{911.6 \text{ A}}{Z^2} \left(\frac{1}{n^2} - \frac{1}{m^2} \right)^{-1}$$

E.g.,

$m = 2, \quad n = 1, \quad Z = 1$

$$\lambda = 911.6 \text{ Å} \left(\frac{1}{1^2} - \frac{1}{2^2} \right)^{-1} = 911.6 \left(\frac{3}{4} \right)^{-1}$$

$$= 911.6 \left(\frac{4}{3} \right) = 1216 \text{ Å}$$

$m = 3, n = 1, Z = 1$

$$\lambda = 911.6 \left(\frac{1}{1^2} - \frac{1}{3^2} \right)^{-1} = 911.6 \left(\frac{8}{9} \right)^{-1}$$

$$= 911.6 \left(\frac{9}{8} \right) = 1026 \text{ Å}$$

Lines that start or end on n=1 are called the "Lyman" series. All are between 911.6 and 1216 A.
$m = 3, n = 2, Z = 1$

$$\lambda = 911.6 \left(\frac{1}{2^2} - \frac{1}{3^2} \right)^{-1} = 911.6 \left(\frac{1}{4} - \frac{1}{9} \right)^{-1}$$

$$= 911.6 \left(\frac{5}{36} \right)^{-1} = 911.6 \left(\frac{36}{5} \right) = 6564 \text{ Å}$$

Lines that start or end on n=2 are called the "Balmer" series. All are between 3646 and 6564 A.

Absorbtion Line Spectrum
When we examine the spectra of stars, with a few exceptions to be discussed later, we see blackbody spectra with a superposition of *absorption* lines.

The identity and intensity of the "spectral lines" that are present reflect the temperature, density and composition of the stellar photosphere.

TABLE P.1 THE COSMICALLY ABUNDANT ELEMENTS

Element	Symbol	Number of Atoms per Million Hydrogen Atoms
Hydrogen	H	1,000,000
Helium	He	68,000
Carbon	C	420
Nitrogen	N	87
Oxygen	O	690
Neon	Ne	98
Magnesium	Mg	40
Silicon	Si	38
Sulfur	S	19
Iron	Fe	34

Reminder: We know the temperature from Wien's Law

Using Wien's Law to Calculate Stellar Temperature

Peak wavelength = 4580 Angstroms
= 458.0 nm
= 4.58 x 10^{-7} m

approximate
Planck
curve

T = W/peak wavelength
so
T = 2.898 x 10^{-3}/4.58 x 10^{-7}
T = 6,300 K

F_λ [10^{-17} erg cm^{-2} s^{-1} Å^{-1}]

Wavelength [Å]
The solar spectrum

C = Balmer alpha
F = Balmer beta
f = Balmer gamma
H, K = ionized calcium
others = Fe, Mg, Na, etc.
Wollaton (1802) discovered dark lines in the solar spectrum. Fraunhaufer rediscovered them (1817) and studied the systematics

As the temperature in a gas is raised, electrons will be removed by collisions and interactions with light. The gas comes *ionized*.

The degree of ionization depends on the atom considered and the temperature.

Notation: Ionization stages

H I   neutral hydrogen   1 p   1 e
H II   ionized hydrogen   1 p   0 e

He I   neutral helium   2 p   2 e
He II   singly ionized helium   2 p   1 e
He III   doubly ionized helium   2 p   0 e

C I   neutral carbon   6 p   6 e
C II C^+ 6 p   5 e
C III C^{++} 6 p   4 e
etc.

The ionization energy is the energy required to remove a single electron from a given ion. The excitation energy is the energy required to excite an electron from the ground state to the first excited state.

Ion	Excitation energy (eV)	Ionization energy (eV)
H I	10.2	13.6
He I	20.9	24.5
He II	40.8	54.4
Li I	1.8	5.4
Ne I	16.6	21.5
Na I	2.1	5.1
Mg I	2.7	7.6
Ca I	1.9	6.1

Li is He plus one proton, Na is Ne plus 1 proton, Ca is Ar plus 2 protons. The noble gases have closed electron shells and are very stable.

Left plot: y-axis "Intensity of Hβ", x-axis "T" with marks at 5000, 10,000, 20,000. Title "(Qualitatively)". Curve peaking near 10,000 labeled "H I" on left side and "H II" on right side.

Right plot: y-axis "Intensity", x-axis "T →". Three overlapping curves labeled "Si I", "Si II", "Si III" with "et" to the right.

Main sequence stars would look like this to the human eye

M K G F A B O
http://en.wikipedia.org/wiki/Stellar_classification

Spectral Sequence
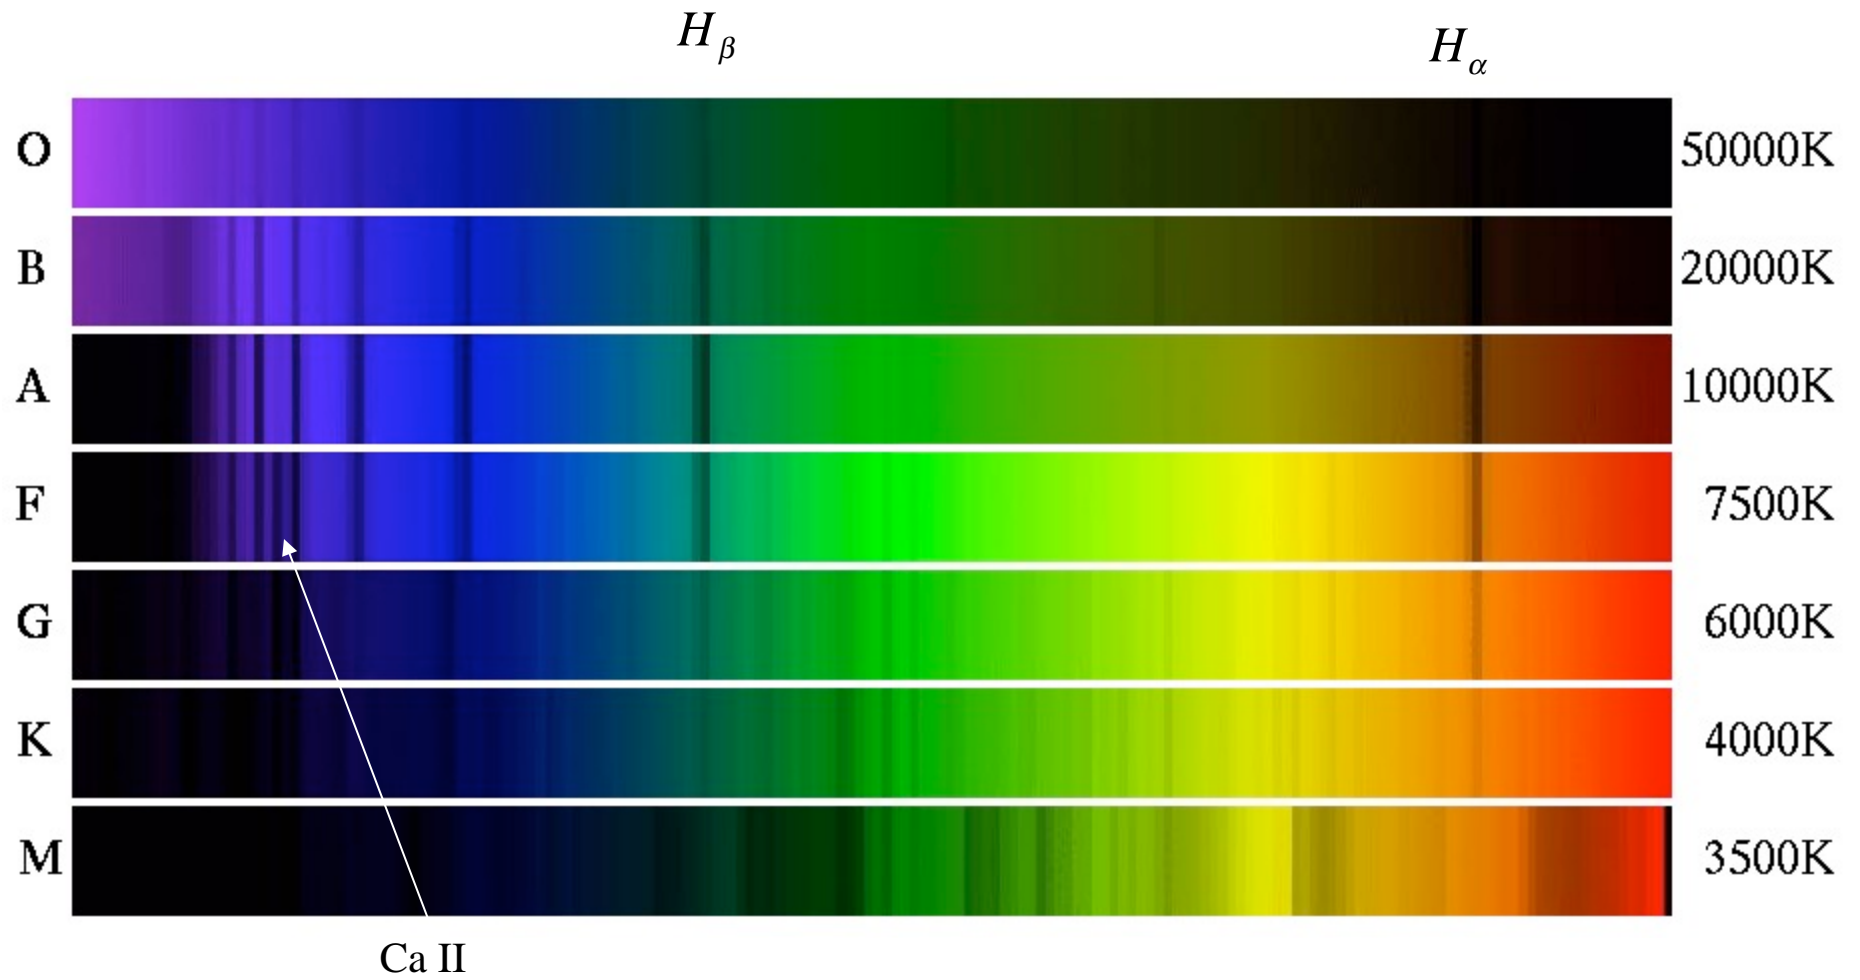

- Cannon further refined the spectral classification system by dividing the classes into numbered subclasses:

- For example, A was divided into

$$A0 \quad A1 \quad A2 \quad A3 \quad ... \quad A9$$

- Between 1911 and 1924, she classified about 220,000 stars, published as the Henry Draper Catalog.
The Henry Draper Spectral Sequence

Spectral Type	Principal Characteristics	Spectral Criteria
O	Hottest blue stars Relatively few lines He II dominates	Strong He II lines—in absorption, sometimes emission. He I lines weak, but increasing in strength from O5 to O9. Hydrogen Balmer lines prominent, but weak compared to later types. Lines of Si IV, O III, N III, and C III.
B	Hot blue stars More lines He I dominates	He I lines dominate, with maximum strength at B2; He II lines virtually absent. Hydrogen lines strengthening from B0 to B9. Also Mg II and Si II lines.
A	Blue stars Ionized metal lines Hydrogen dominates	The hydrogen lines reach maximum strength at A0. Lines of ionized metals (Fe II, Si II, Mg II) at maximum strength near A5. Ca II lines strengthening. The lines of neutral metals are appearing weakly.

|		
F	White stars Hydrogen lines declining Neutral metal lines increasing	The hydrogen lines are weakening rapidly, while the H and K lines of Ca II strengthen. Neutral metal (Fe I and Cr I) lines gaining on ionized metal lines by late F.
G	Yellow stars Many metal lines Ca II lines dominate	The hydrogen lines are very weak. The Ca II H and K lines reach maximum strength near G2. Neutral metal (Fe I, Mn I, Ca I) lines strengthening, while ionized metal lines diminish. The molecular G-band of CH becomes strong.
K	Reddish stars Molecular bands appear Neutral metal lines dominate	The hydrogen lines are almost gone. The Ca lines are strong. Neutral metal lines are very prominent. By late K the molecular bands of TiO begin to appear.
M	Coolest red stars Neutral metal lines strong Molecular bands dominate	The neutral metal lines are very strong. Molecular bands are prominent, with the TiO bands dominating the spectrum by M5. Vanadium oxide (VO) bands appear.

Summary of spectroscopic types

Class	Temperature[8] (kelvins)	Conventional color	Apparent color[9][10][11]	Mass[8] (solar masses)	Radius[8] (solar radii)	Luminosity[8] (bolometric)	Hydrogen lines	Fraction of all main sequence stars[12]

DISTINGUISHING MAIN SEQUENCE STARS

The surface gravity
$$g = \frac{GM}{R^2}$$

of a star is clearly larger for a smaller radius (if M is constant)

To support itself against this higher gravity, a the stellar photosphere must have a larger pressure. As we shall see later for an ideal gas
$$P = n\,k\,T$$
where n is the number density and T is the temperature. If two stars have the same temperature, T, the one with the higher pressure (smaller radius) will have the larger n, i.e., its atoms will be more closely crowded together. This has two effects:

1) At a greater density (and the same T) a gas is less ionized

2) If the density is high, the electrons in one atom "feel" the presence of other nearby nuclei. This makes their binding energy less certain. This spreading of the energy level is called "Stark broadening"
A3 I   Comparison of Spectral Lines for Supergiant & Main Sequence Stars

— Thinner lines —

A3 V

Pressure broadening of lines

A3 I (supergiant)

Narrow line, low density

A3 V (Main sequence)

Broad line, higher density

Note: Surface gravity on the main sequence is higher for *lower* mass stars

$$R \propto M^{0.65}$$

$$\frac{GM}{R^2}$$ decreases with increasing M

All 3 stars have the same temperature but,
- The supergiants have the narrowest absorption lines
- Small Main-Sequence stars have the broadest lines
- Giants are intermediate in line width and radius

- In 1943, Morgan & Keenan added the *Luminosity Class* as a second classification parameter:
  - Ia = Bright Supergiants
  - Ib = Supergiants
  - II = Bright Giants
  - III = Giants
  - IV = Subgiants
  - V = Main sequence

Luminosity Classes
